Learning

Learning goals

- Trace + implement **passive adaptive dynamic programming** (passive ADP).
- Explain the **exploration vs exploitation** trade-off.
- Trace + implement **active ADP**.
- Trace + implement **Q-learning**.
- Trace + implement **SARSA**.
- Tell **on-policy** from **off-policy** learning.

The RL setting: no P , no R up front

An MDP whose **transition P** and **reward R** are unknown. The agent sees state s and reward r , picks an action a , and observes s' . Goal: maximize discounted return.

Three new challenges:

- **Credit assignment:** which past action caused this reward?
- **Long-term impact:** how will this action affect future returns?
- **Explore vs exploit:** try new actions or stick with the best known?

Passive learning: just evaluate a fixed policy

Fix a policy π . Goal: learn $V^\pi(s)$ for every state s .

Adaptive Dynamic Programming (ADP)

1. **Learn** the transition $P(s' \mid s, a)$ and reward $R(s)$ from observed experience.
2. **Solve** the Bellman policy-evaluation equations:

$$V^\pi(s) = R(s) + \gamma \sum_{s'} P(s' \mid s, \pi(s)) V^\pi(s').$$

A **model-based** approach — it builds an explicit model of the world.

The passive ADP algorithm

passive-ADP(π)

1. Initialize $R(s)$, $N(s, a)$, $N(s, a, s')$, $V^\pi(s)$.
2. Follow π and observe an experience $\langle s, a, s', r \rangle$.
3. Update reward: $R(s) \leftarrow r$.
4. Update counts and transition probability:

$$N(s, a) += 1, \quad N(s, a, s') += 1, \quad P(s' \mid s, a) = \frac{N(s, a, s')}{N(s, a)}.$$

5. Re-solve Bellman to get $V^\pi(s)$ (exactly or iteratively).

Each new experience refines the model; each Bellman solve costs $O(n^3)$ or a few iterations.

Passive ADP: a worked example

s_{11}	+1
s_{21}	-1

$\pi(s_{11}) = \text{down}, \pi(s_{21}) = \text{right}, \gamma = 0.9.$

Before: $N(s, a) = 5$ for all s, a ; $N(s, a, s') = 3$ for intended direction, 1 for each side.

New experience: $\langle s_{11}, \text{down}, s_{21}, -0.04 \rangle$.

Update counts: $N(s_{11}, \text{down}) = 6, N(s_{11}, \text{down}, s_{21}) = 4.$

Solve Bellman with the refreshed model:

$$V(s_{11}) = -0.4378, \quad V(s_{21}) = -0.8034.$$

Quick check: probability update

Q1. In a 3x4 grid, suppose $N(s_{23}, \text{down}) = 23$ and $N(s_{23}, \text{down}, s_{24}) = 2$. The agent tries to move *down* but slips and lands in s_{24} . What is the updated $P(s_{24} \mid s_{23}, \text{down})$?

- A. $2/23 \approx 0.087$
- B. $3/23 \approx 0.130$
- C. $3/24 = 0.125$
- D. $2/24 \approx 0.083$

C — 0.125. First increment the counts: $N(s_{23}, \text{down}) \rightarrow 24$ and $N(s_{23}, \text{down}, s_{24}) \rightarrow 3$. Then $P = 3/24 = 0.125$.

Active learning: explore vs exploit

Now the agent *chooses* its actions. Two competing pressures:

Exploit

Take the action that maximizes the current $V(s)$ (or $Q(s, a)$). Reap known rewards.

Explore

Try a different action. Gather data to learn a better model / better Q-values.

A purely greedy agent *seldom* converges to the optimal policy — the learned model is biased toward states the agent has already preferred.

Three exploration strategies

ϵ -greedy

Random with prob ϵ ;
greedy with prob $1 - \epsilon$.

Decay ϵ over time.

Simple, but treats all sub-optimal actions equally.

Softmax / Boltzmann

$$P(a) = \frac{e^{Q(s,a)/T}}{\sum_{a'} e^{Q(s,a')/T}}$$

Low T : peaky / greedy. High T :
uniform / exploratory.

Optimistic init

$$f(u, n) = \begin{cases} R^+ & n < N_e \\ u & \text{else} \end{cases}$$

"Shiny new toy" bonus until
each action has been tried N_e
times.

The active ADP algorithm

$$\text{active-ADP}(N_e, R^+)$$

1. Initialize $R(s)$, $V^+(s)$, $N(s, a)$, $N(s, a, s')$.
2. Repeat until every (s, a) is visited $\geq N_e$ times and V^+ converged:
 - Pick action $a = \arg \max_a f(\sum_{s'} P(s' | s, a) V^+(s'), N(s, a))$.
 - Execute a ; observe $\langle s, a, s', r \rangle$; update $R(s) \leftarrow r$, counts, and $P(s' | s, a)$.
 - Update $V^+(s) \leftarrow R(s) + \gamma \max_a f(\sum_{s'} P(s' | s, a) V^+(s'), N(s, a))$.

Same model-based loop as passive ADP, plus the exploration bonus f baked into action selection.

From V to Q : learn without a model

Bellman for V and Q are both fixed-point equations:

Bellman for $V^\star$

$$V^\star(s) = R(s) + \gamma \max_a \sum_{s'} P(s' | s, a) V^\star(s')$$

To pick $\pi^\star$ you still need to know P and combine it with $V^\star$.

Bellman for $Q^\star$

$$Q^\star(s, a) = R(s) + \gamma \sum_{s'} P(s' | s, a) \max_{a'} Q^\star(s', a')$$

If we know $Q^\star$, then $\pi^\star(s) = \arg \max_a Q^\star(s, a)$ – no P needed.
model-free!

Learning Q directly is the trick that makes RL practical at scale.

Temporal difference (TD) error

After one transition $\langle s, a, r, s' \rangle$, pretend that transition was certain ($P(s' | s, a) = 1$). Then by Bellman:

$$Q(s, a) \stackrel{?}{=} \underbrace{R(s) + \gamma \max_{a'} Q(s', a')}_{\text{target}}$$

TD error

$$\delta = \left(R(s) + \gamma \max_{a'} Q(s', a') \right) - Q(s, a)$$

Idea: nudge $Q(s, a)$ toward the target by an amount proportional to δ .

The Q-learning algorithm

Q-learning(α, γ)

1. Initialize $Q(s, a)$ arbitrarily, $R(s)$, $N(s, a)$.
2. Repeat until Q converges:
 - Pick a from s using *any* exploration strategy (ϵ -greedy, softmax, optimistic).
 - Execute a ; observe $\langle s, a, s', r \rangle$; update $R(s) \leftarrow r$.
 - $Q(s, a) \leftarrow Q(s, a) + \alpha(r + \gamma \max_{a'} Q(s', a') - Q(s, a))$.
 - $s \leftarrow s'$.
- **Model-free:** never estimates P explicitly.
- **Learning rate:** smaller α = slower but more accurate; e.g. $\alpha(N) = 10/(9 + N(s, a))$.
- Converges to Q^* if every (s, a) is visited infinitely often.

Q-learning: a single update

3x4 grid. Experience: $\langle s_{32}, \text{right}, s_{33}, -0.04 \rangle$. Take $\gamma = 1, \alpha = 0.1$.

	s_{32}	s_{33}
up	0.55	0.4
right	0.7	0.9
down	0.5	0.8
left	0.4	0.5

Yellow cell = the one we update; green = the max-value action in s_{33} .

$$\text{target} = r + \gamma \cdot \max_{a'} Q(s_{33}, a') = -0.04 + 1.0 \cdot 0.9 = 0.86$$

$$\delta = \text{target} - Q(s_{32}, \text{right}) = 0.86 - 0.7 = 0.16$$

$$Q(s_{32}, \text{right}) \leftarrow 0.7 + 0.1 \cdot 0.16 = 0.716$$

SARSA: on-policy temporal difference

Observe a 5-tuple $\langle s, a, r, s', a' \rangle$ where a' is the action **actually taken** in s' (per the current policy):

Q-learning (off-policy)

$$Q(s, a) \leftarrow Q(s, a) + \alpha (r + \gamma \max_{a'} Q(s', a') - Q(s, a))$$

Target uses the *greedy* next action. Learns about the optimal policy regardless of what's actually played.

SARSA (on-policy)

$$Q(s, a) \leftarrow Q(s, a) + \alpha (r + \gamma Q(s', a') - Q(s, a))$$

Target uses the *actually-played* next action a' . Learns about the policy the agent is following (exploration and all).

SARSA = State, Action, Reward, State, Action.

SARSA vs Q-learning: a side-by-side update

Suppose we're at s_{13} ; we'll update $Q(s_{13}, \text{down}) = 0.4$. The next state is s_{23} , with $Q(s_{23}, \cdot) = (\text{left} : 0.3, \text{right} : -0.4, \text{down} : 0.7, \text{up} : 0.3)$. Reward $r = -0.04, \gamma = 0.9, \alpha = 0.4$.

Now suppose ϵ -greedy samples $a' = \text{right}$ at s_{23} (an exploration step into the bad cell).

SARSA: uses $a' = \text{right}$

$$\begin{aligned} \text{target} &= -0.04 + 0.9 \cdot Q(s_{23}, \\ &\text{right}) = -0.04 + 0.9 \cdot (-0.4) = \\ &-0.4 \end{aligned}$$

$$\delta = -0.4 - 0.4 = -0.8$$

$$\begin{aligned} Q(s_{13}, \text{down}) &\leftarrow 0.4 + 0.4 \cdot \\ &(-0.8) \end{aligned}$$

$$= 0.08 \quad (\text{punished for the actual})$$

Q-learning: uses $\max_{a'} = 0.7$

$$\begin{aligned} \text{target} &= -0.04 + 0.9 \cdot \max \\ Q(s_{23}, \cdot) &= -0.04 + 0.9 \cdot 0.7 = \\ &0.59 \end{aligned}$$

$$\delta = 0.59 - 0.4 = 0.19$$

$$Q(s_{13}, \text{down}) \leftarrow 0.4 + 0.4 \cdot 0.19$$

$$= 0.476 \quad (\text{rewarded for the optimistic best})$$

ADP vs Q-learning vs SARSA

	ADP	Q-learning	SARSA
Learns transition P ?	yes (model-based)	no (model-free)	no (model-free)
On / off policy	n/a (eval-only)	off-policy	on-policy
Computation per experience	heavy (solve Bellman)	cheap (one TD update)	cheap (one TD update)
Convergence speed	fast (few experiences)	slower, higher variance	slower, higher variance

ADP is sample-efficient but expensive per step; TD methods (Q, SARSA) flip that trade-off.

When to use what (Q2)

Q2. For a high-stakes *online* learning problem (for example, a self-driving car still in training), which algorithm is safer?

- A. Q-learning
- B. **SARSA**
- C. I don't know

B — SARSA. SARSA's target uses the action that will *actually* be taken while exploring, so it learns to avoid catastrophic outcomes along the exploration path. Q-learning's target uses the greedy action, ignoring the cost of exploration mistakes.

Putting the labels together (Q3)

Q3. Which statement is true?

- A. Q-learning is model-free + off-policy; SARSA is model-based + on-policy.
- B. Q-learning is model-based + off-policy; SARSA is model-free + on-policy.
- C. Q-learning is model-free + on-policy; SARSA is model-based + off-policy.
- D. Q-learning is model-based + on-policy; SARSA is model-free + off-policy.
- E. **None of the above.**

E — None of the above. Both Q-learning and SARSA are *model-free*. Q-learning is off-policy (target uses $\max_{a'} Q$); SARSA is on-policy (target uses the action actually played).

Learning goals (recap)

- ✓ Trace + implement **passive ADP**.
- ✓ Explain the **exploration vs exploitation** trade-off.
- ✓ Trace + implement **active ADP**.
- ✓ Trace + implement **Q-learning**.
- ✓ Trace + implement **SARSA**.
- ✓ Tell **on-policy** from **off-policy**.
